Naturally Acquired *Sarcoptes scabiei* Infestation in a Captive Southern Tamandua (*Tamandua tetradactyla*) and a Capybara (*Hydrochoeris hydrochaeris*)

**Abstract**

A privately-owned southern tamandua (*Tamandua tetradactyla*) and a capybara (*Hydrochoeris hydrochaeris*) were presented for severe pruritus. Superficial skin scrapings revealed numerous *Sarcoptes scabiei* mites. Morphological examination and mitochondrial DNA sequencing revealed that both patients were infested with *Sarcoptes scabiei*. The animals were treated with selamectin (9 mg/kg) topically once, and the owner was instructed to repeat treatment in two weeks. The tamandua died of unknown causes three weeks after initial examination before reevaluation could occur. Clinical signs and skin lesions in the capybara resolved after two treatments with selamectin. This is the first documented report of sarcoptic mange in a southern tamandua. In addition, this is the first documented case of natural transmission of *Sarcoptes* mites between a tamandua and capybara in captivity. Finally, this is the first described use of topical selamectin for the treatment and resolution of sarcoptic mange in a capybara.

**Keywords:** Capybara; *Hydrochoeris hydrochaeris*; Lesser anteater; Selamectin; Scabies; *Tamandua tetradactyla*

**Case Report**

*Sarcoptes scabiei* was first a human parasite that spread to various domestic and captive animal hosts, and later moved to certain wildlife species, especially canids, felids, and bovids [1]. *Sarcoptes* mites recovered from different hosts are indistinguishable morphologically, and genetic analyses show that the genus *Sarcoptes* contains a variable single species with several host-adapted strains [1]. Clinically, sarcoptic mange is characterized by severe pruritus, papules, alopecia, crusts, excoriations, and lichenification [2-9], which may become generalized in chronic cases, but typically, lesions concentrate at elbows, hocks, pinna margins, and ventral abdomen [10]. Infestations are most common in crowded, unclean settings, where they are highly contagious. The mite is difficult to diagnose unless the animal is heavily infested, most tests lack sensitivity, and superficial skin scrapings may yield mites only 20% of the time [3].

The southern tamandua, or lesser anteater (*Tamandua tetradactyla*), is a forest-dwelling species native to South America [11] Common typical ectoparasites are ticks, psoroptid mites, and fleas [12-14]. Tamanduas are frequently exhibited in zoos, and less commonly, owned privately as pets. The capybara (*Hydrochoeris hydrochaeris*) is a large rodent inhabiting riverbanks and marshlands in Central and South America. They also are common in zoos or privately owned for exhibition. At least 19 tick species

---

infest wild capybaras, and captive animals commonly sustain sarcoptic mange [2,7].

Case 1

A 3-year-old female intact southern tamandua presented for a 3-week history of pruritus and an exudative excoriation on the right flank. The animal was housed in a 2 × 1 × 2 m wire cage with aluminum flooring, bedded with pine shavings. The patient’s cage was kept in a room shared with a capybara but these animals never contacted each other directly. On physical examination, multifocal crusts and scale were observed at the base of the pinnae, axillae, elbows, and inguinal region. A 4 × 4 cm erythematous excoriated patch on the right flank (Figure 1) exuded serosanguinous discharge centrally, with peripheral crusting. The interdigital spaces were severely erythemic and moist. Patchy hypotrichosis was noted in the interscapular space, over the right shoulder, and on the dorsal surface of the muzzle. The patient was observed to be pruritic during the examination. An impression smear was acquired from the right flank. Hair was plucked from multiple areas for trichogram, and a sample for dermatophyte fungal culture was acquired via the Mckensie toothbrush technique. A crust at the cranial margin of the excoriation was lifted and the area underneath swabbed for bacterial and fungal cultures. Skin scrapings were performed at multiple affected sites.

Skin cytology revealed neutrophilic inflammation, with intra and extracellular coccoïd and rod-shaped bacteria. No parasites or fungal agents were observed on trichogram, and dermatophyte test media revealed no growth after one month. Bacterial culture revealed heavy mixed growth of several species, including Staphylococcus aureus, Proteus mirabilis, Corynebacterium spp., and two species of Streptococcus, while fungal culture yielded a heavy growth of Candida albicans. Skin scrapings taken from the left elbow and right inguinal fold revealed Sarcoptes scabiei. Subsequent standard tissue maceration, flotation, and microscopic examination of slide-mounted mites (Figure 3) confirmed the identification. Other skin scrapings were collected for molecular analysis. The capybara was treated with selamectin (Zoetis; 9 mg/kg topically, once) and following manufacturer’s protocol.

DNA was extracted from skin scrapings obtained from both hosts, using the DNeasy Blood and Tissue Kit (QIAGEN Inc., Valencia, California 91355, USA) and following manufacturer’s protocol. DNA was eluted in 200 µL of water and stored at -20°C. 700 base pairs of the mitochondrial cytochrome C oxidase subunit 1 (Cox1) were amplified in 50 µL reactions, using 2 µL of DNA, 3 mmol

Clinical photograph, Case 2. Sarcoptic mange; diffuse erythema, hypotrichosis to alopecia, with scaling and focal crusting along the face, distal extremities, and ventral surfaces of a capybara (Hydrochoerus hydrochaeris).
of MgCl₂, 200 µmol of dNTPs, 1× PCR buffer, 2 units of Taq DNA Polymerase (Promega Corp., Madison, Wisconsin 53704, USA), and 2.5 µmol each of primers 5’-GACACCCAGAAGTTACATT-3’ and 5’-TATAATTTGATAATGAACTC-3’ [6]. Thermocycling conditions with denaturation at 94°C for 2 min, 5 cycles of 94°C for 15 s, 45°C for 15 s, 72°C for 1 min, followed by 30 cycles of 94°C for 15 s, 50°C for 15 s, 72°C for 1 min, and a final extension step of 72°C for 5 min.

Presence of amplification products was confirmed with agarose gel electrophoresis on 1.5% gels. Products were purified using the Wizard SV Gel and PCR Clean-Up System (Promega). Sequencing was performed on an Applied Biosystems 3730xl DNA Analyzer. Trimming and pairwise sequence alignments were conducted using MEGA6.06 [13]. Nucleotide BLAST searches were performed to compare sequences with those in NCBI GenBank. Sequences were deposited in GenBank (BankIt1952082 CapCox1*KK827305, AntCox1 KK827306). Partial Cox1 sequences obtained after sequencing were trimmed to 543 bp. Pairwise sequence alignment of the partial Cox1 gene of Sarcoptes derived from both hosts revealed 100% mutual identity. BLAST results revealed that the sequences had 99.63% identity with S. scabiei types suis and canis; 99.44% identity with S. scabies types vulpes, wallaby and wombati; 99.26% identity with S. scabiei types hominis and oxytologus 2; and 99.08% identity with S. scabiei type oxytologus 2.

This report describes the first documented case of sarcoptic mange in an anteater and the evident transmission of mites between a captive capybara and a tamandua. Despite unsubstantiated generic mentions of S. scabiei from anteaters in two review papers, [4,8] there are no previous, verified primary reports of sarcoptic mange in any member of the Vermilingua, although the mites do infest certain other pilosans [12].

Microscopy and genetic sequencing confirmed that the mites recovered from both patients were S. scabiei. The source of these mites remains unknown, but they were genetically identical between the two patients, indicating transmission among these exotic hosts or infestation from a common source. Considering that individual strains of S. scabiei are highly host adapted, transmission from one exotic species to another completely unrelated species is unusual. The genetic similarity between the mites recovered from these cases and those posted to GenBank are most compatible the canid or suid type mite, although the sequences are not 100% identical. Both patients were part of a collection used in a traveling show for entertainment and educational purposes, but neither had been exhibited at any venues for months prior to diagnosis. Both patients had resided with the owner for two years, and their origin was not disclosed.

The efficacy of selamectin for treatment of sarcoptic mange in the tamandua is undetermined because the animal died before re-examination. However, rare mites were seen on the skin during necropsy. The owner did not report any adverse effects such as vomiting, diarrhea, ataxia or seizures prior to the tamandua being found deceased. The presence of renal tubular degeneration and hemorrhage found within the gastrointestinal tract could represent an unrelated cause of death or be due to autolysis post-mortem, but neither is consistent with reported selamectin toxicity. Although post-treatment skin scrapings for the capybara were not performed, client communication indicated complete clinical resolution following two doses of selamectin applied topically two weeks apart.

Sarcoptes scabiei is capable of infesting both the capybara and Southern tamandua, resulting in pruritus and classical lesions associated with sarcoptic mange. Circumstances suggest that these mites can be transmitted between proximately housed host species, and they may have further zoonotic potential. Topical treatment with selamectin may provide a viable treatment option in future cases.
